The Transition to Grandparenthood and its Impact on the Big Five Personality Traits and Life Satisfaction

Becoming a grandmother or grandfather is a pivotal life event for many people in 42 midlife or old age (Infurna et al., 2020). At the same time, there is considerable 43 heterogeneity in how intensely grandparents are involved in their grandchildren's lives and care (Mever & Kandic, 2017). In view of an aging demographic, the time that grandparents are alive and in good health during grandparenthood is prolonged compared to previous generations (Leopold & Skopek, 2015; Margolis & Wright, 2017). In addition, an increased share of childcare functions are being fulfilled by grandparents (Hayslip et al., 2019; Pilkauskas et al., 2020). Thus, intergenerational relations have received heightened attention from psychological and sociological research in recent years (Bengtson, 2001; Coall & Hertwig, 2011). With regard to personality development, the transition to grandparenthood has been posited as an important developmental task in old age (Hutteman et al., 2014). However, empirical research into the psychological consequences of becoming a grandparent is sparse. Testing hypotheses derived from neo-socioanalytic theory (Roberts & Wood, 2006) in a prospective matched control-group design (see Luhmann et al., 2014), we investigate whether the transition to grandparenthood affects the Big Five personality traits and life satisfaction using data from two nationally representative panel studies.

Personality Development in Middle Adulthood and Old Age

The life span perspective characterizes aging as a lifelong process of development and adaptation (Baltes et al., 2006). In accordance with this perspective, research has found personality traits to be subject to change throughout the entire life span (Costa et al., 2019; Graham et al., 2020; Specht, 2017; Specht et al., 2014). Although a major portion of personality development takes place in adolescence and emerging adulthood (Bleidorn & Schwaba, 2017; Schwaba & Bleidorn, 2018), evidence has accumulated that

```
personality traits also undergo changes in middle and old adulthood (e.g., Damian et al.,
   2019; Kandler et al., 2015; Lucas & Donnellan, 2011; Mõttus et al., 2012; Wagner et al.,
67
   2016; for a review, see Specht, 2017).
68
          Here, we examine the Big Five personality traits—agreeableness, conscientiousness,
69
   extraversion, neuroticism, and openness to experiences—which constitute a broad
70
   categorization of universal patterns of thought, affect, and behavior (John et al., 2008).
71
   While the policy relevance of the Big Five personality traits has recently been emphasized
72
   (Bleidorn et al., 2019)—especially because of their predictive power regarding many
73
   important life outcomes (Ozer & Benet-Martínez, 2005; Roberts et al., 2007; Soto, 2019),
   we acknowledge that there are other viable taxonomies of personality (Ashton & Lee, 2007)
   and other levels of breadth and scope that could add valuable insights to personality
   development in middle adulthood and old age (Mõttus et al., 2017; Mõttus & Rozgonjuk,
   2021).
          Changes over time in the Big Five occur both in mean trait levels (i.e., mean-level
79
   change; Roberts et al., 2006) and in the relative ordering of people to each other on trait
   dimensions (i.e., rank-order stability; Anusic & Schimmack, 2016; Roberts & DelVecchio,
81
   2000). No observed changes in mean trait levels do not necessarily mean that individual
   trait levels are stable over time, and perfect rank-order stability does not preclude
   mean-level changes. Mean-level changes in middle adulthood (ca. 30–60 years old;
84
   Hutteman et al., 2014) are typically characterized in terms of greater maturity as
85
   evidenced by increased agreeableness and conscientiousness, and decreased neuroticism
   (Damian et al., 2019; Roberts et al., 2006). In old age (ca. 60 years and older; Hutteman
87
   et al., 2014), research is generally more sparse but there is some evidence for a reversal of
   the maturity effect, especially following retirement (sometimes termed la dolce vita effect;
   Marsh et al., 2013; cf. Schwaba & Bleidorn, 2019) and at the end of life in ill health
   (Wagner et al., 2016).
91
          In terms of rank-order stability, some prior studies have shown support for an
```

inverted U-shape trajectory (Ardelt, 2000; Lucas & Donnellan, 2011; Specht et al., 2011; Wortman et al., 2012): Rank-order stability rises until reaching a plateau in midlife, and decreases, again, in old age. However, evidence is mixed whether rank-order stability 95 actually decreases again in old age (see Costa et al., 2019). Nonetheless, the historical view that personality is stable, or "set like plaster" (Specht, 2017, p. 64) after one reaches 97 adulthood (or leaves emerging adulthood behind; Bleidorn & Schwaba, 2017) can largely be abandoned (Specht et al., 2014). 99

Theories explaining the mechanisms of personality development in middle adulthood 100 and old age emphasize both genetic influences and life experiences as interdependent 101 sources of stability and change (Specht et al., 2014; Wagner et al., 2020). We focus on the 102 latter¹ and conceptualize the transition to grandparenthood as a life experience that offers 103 the adoption of a new social role according to the social investment principle of neo-socioanalytic theory (Lodi-Smith & Roberts, 2007; Roberts & Wood, 2006). According 105 to the social investment principle, normative life events or transitions such as entering the 106 work force or becoming a parent lead to personality maturation through the adoption of 107 new social roles (Roberts et al., 2005). These new roles encourage or compel people to act 108 in a more agreeable, conscientious, and emotionally stable (i.e., less neurotic) way, and the 109 experiences in these roles as well as societal expectations towards them are hypothesized to 110 drive long-term personality development (Lodi-Smith & Roberts, 2007; Wrzus & Roberts, 111 2017). Conversely, consistent social roles foster personality stability. 112

The paradoxical theory of personality coherence (Caspi & Moffitt, 1993) offers 113 another explanation for personality development through role shifts stating that trait change is more likely whenever people transition into unknown environments where 115 pre-existing behavioral responses are no longer appropriate and societal norms or social 116 expectations give clear indications how to behave instead. On the other hand, stability is 117

¹ In a behavior-genetic twin study, Kandler et al. (2015) found that non-shared environmental factors were the main source of personality plasticity in old age.

favored in environments where no clear guidance how to behave is available. Thus, the finding that age-graded, normative life experiences such as possibly the transition to grandparenthood drive personality development would also be in line with the paradoxical theory of personality coherence (see Specht et al., 2014).

Certain life events such as the first romantic relationship (Wagner et al., 2015) or 122 the transition from high school to university (Lüdtke et al., 2011) have (partly) been found 123 to be accompanied by mean-level increases in line with the social investment principle (for 124 a review, see Bleidorn et al., 2018). However, recent evidence regarding the transition to 125 parenthood failed to empirically support the social investment principle (Asselmann & 126 Specht, 2020; van Scheppingen et al., 2016). An analysis of monthly trajectories of the Big 127 Five before and after nine major life events only found limited support for the social 128 investment principle: small increases were found in emotional stability following the transition to employment but not for the other traits or for the other life events 130 theoretically linked to social investment (Denissen et al., 2019). Recently, it has also been 131 emphasized that effects of life events on the Big Five personality trends generally tend to 132 be small and need to be properly analyzed using robust, prospective designs and 133 appropriate control groups (Bleidorn et al., 2018; Luhmann et al., 2014). 134

Overall, much remains unknown regarding the environmental factors underlying 135 personality development in middle adulthood and old age. One indication that age-graded, 136 normative life experiences contribute to change following a period of relative stability in 137 midlife is offered by recent research on retirement (Bleidorn & Schwaba, 2018; Schwaba & 138 Bleidorn, 2019). These results were only partly in line with the social investment principle 130 in terms of mean-level changes and displayed substantial individual differences in change 140 trajectories. The authors discuss that as social role "divestment" (Schwaba & Bleidorn, 141 2019, p.?) retirement functions differently compared to social investment in the classical 142 sense which adds a role. The transition to grandparenthood could represent such an 143 investment into a new role in middle adulthood and old age—given that grandparents have regular contact with their grandchild and actively take part in childcare to some degree (i.e., invest psychologically in the new grandparent role; Lodi-Smith & Roberts, 2007).

47 Grandparenthood

170

The transition to grandparenthood, that is, the birth of the first grandchild, can be 148 described as a time-discrete life event marking the beginning of one's status as a grandparent (Luhmann et al., 2012). In terms of characteristics of major life events 150 (Luhmann et al., 2020), the transition to grandparenthood stands out in that it is 151 externally caused (by one's own children; see also Arpino, Gumà, et al., 2018; Margolis & 152 Verdery, 2019), while at the same time being predictable as soon as one's children reveal 153 their pregnancy or family planning. The transition to grandparenthood has been labeled a 154 countertransition due to this lack of direct control over if and when someone has their first 155 grandchild (Hagestad & Neugarten, 1985; as cited in Arpino, Gumà, et al., 2018). 156 Grandparenthood is also generally positive in valence and emotionally significant—given 157 one maintains a good relationship with their child. 158 Grandparenthood can also be characterized as a developmental task (Hutteman et 159 al., 2014) mostly associated with the period of (early) old age—although considerable 160 variation in the age at the transition to grandparenthood exists both within and between 161

al., 2014) mostly associated with the period of (early) old age—although considerable variation in the age at the transition to grandparenthood exists both within and between cultures (Leopold & Skopek, 2015; Skopek & Leopold, 2017). Still, the period where parents on average experience the birth of their first grandchild coincides with the end of (relative) stability in terms of personality development in midlife (Specht, 2017), where retirement, shifting social roles, and initial cognitive and health declines can potentially be disruptive to life circumstances putting personality development into motion (e.g., Mueller et al., 2016; Stephan et al., 2014). As a developmental task, grandparenthood is expected to be part of a normative sequence of aging that is subject to societal expectations and values differing across cultures and historical time (Baltes et al., 2006; Hutteman et al., 2014).

Mastering developmental tasks (i.e., fulfilling roles and expectations to a high

degree) is hypothesized to drive personality development towards maturation similarly to propositions by the social investment principle, that is, leading to higher levels of 172 agreeableness and conscientiousness, and lower levels of neuroticism (Roberts et al., 2005; 173 Roberts & Wood, 2006). In comparison to the transition to parenthood which has been 174 found to be ambivalent in terms of both personality maturation and life satisfaction 175 (Krämer & Rodgers, 2020; van Scheppingen et al., 2016), Hutteman et al. (2014) 176 hypothesize that the transition to grandparenthood is generally seen as positive because it 177 (usually) does not impose the stressful demands of daily childcare on grandparents. 178 Grandparental investment in their grandchildren has been discussed as beneficial in terms 179 of the evolutionary, economic, and sociological advantages it provides for the whole 180 intergenerational family structure (Coall et al., 2018; Coall & Hertwig, 2011). 181 While we could not find prior studies investigating development of the Big Five over 182 the transition to grandparenthood, there is some evidence on life satisfaction. We define 183 life satisfaction as the general, cognitive appraisal of one's well-being in life based on subjective criteria (Eid & Larsen, 2008). Previous research on associations of 185 grandparenthood with life satisfaction has often relied on cross-sectional designs (e.g., 186 Mahne & Huxhold, 2014; Triadó et al., 2014). There are a few studies with longitudinal 187 designs although with conflicting conclusions: Longitudinal studies utilizing panel data 188 from the Survey of Health, Ageing and Retirement in Europe (SHARE) showed that the 189 birth of a grandchild was followed by improvements to quality of life and life satisfaction 190 only among women (Tanskanen et al., 2019), and only in first-time grandmothers via their 191 daughters (Di Gessa et al., 2019). Several studies emphasized that grandparents actively 192 involved in childcare experienced larger increases in life satisfaction (Arpino, Bordone, et 193 al., 2018; Danielsbacka et al., 2019; Danielsbacka & Tanskanen, 2016). On the other hand, 194 fixed effects regression models² using SHARE data did not find any effects of first-time

 $^{^2}$ Fixed effects regression models exclusively rely on within-person variance (see Brüderl & Ludwig, 2015; McNeish & Kelley, 2019).

grandparenthood on life satisfaction regardless of grandparental investment and only minor decreases of grandmothers' depressive symptoms (Sheppard & Monden, 2019).

In a similar vein, some prospective studies reported beneficial effects of the transition to grandparenthood and of grandparental childcare investment on various health measures, especially in women (Chung & Park, 2018; Condon et al., 2018; Di Gessa et al., 2016a, 2016b). Again, beneficial effects on self-rated health did not persevere in fixed effects analyses as reported in Ates (2017) who used longitudinal data from the German Aging Survey (DEAS).

204 Current Study

210

211

Three research questions motivate the current study which is the first to analyze personality development over the transition to grandparenthood with regards to the Big Five traits:

- 1. What are the effects of the transition to grandparenthood on mean-level trajectories of the Big Five traits and life satisfaction?
 - 2. How large are interindividual differences in intraindividual change for the Big Five traits and life satisfaction over the transition to grandparenthood?
- 3. How does the transition to grandparenthood affect rank-order stability of the Big
 Five traits and life satisfaction?

To address these questions, we compare development over the transition to grandparenthood with that of matched participants who do not experience the transition during the study period (Luhmann et al., 2014). This is necessary because pre-existing differences between prospective grandparents and non-grandparents in variables related to the development of the Big Five or life satisfaction introduce confounding bias when estimating the effects of the transition to grandparenthood (VanderWeele et al., 2020). The impact of adjusting (or not adjusting) for pre-existing differences, or background

characteristics, has recently been emphasized in the prediction of life outcomes from personality in a mega-analytic framework of ten large panel studies (Beck & Jackson, 222 2021). Propensity score matching is one technique to account for confounding bias by 223 equating the groups in their estimated propensity to experience the event in question 224 (Thoemmes & Kim, 2011). This propensity is calculated from regressing the so-called 225 treatment variable (i.e., the group variable indicating whether someone experienced the 226 event) on covariates related to the likelihood of experiencing the event and to the 227 outcomes. Thereby, in addressing confounding bias balance between the groups in the 228 covariates used to calculate the propensity score is also aimed for (Stuart, 2010). 220

We adopt a prospective design that tests effects of first-time grandparents 230 separately against two propensity-score-matched control groups: first, a matched control 231 group of parents (but not grandparents) with at least their oldest child in reproductive age, 232 and, second, a matched control group of nonparents. This allows us to disentangle 233 potential effects attributable to becoming a grandparent from effects attributable to being a parent already, thus addressing selection effects into grandparenthood and confounding 235 more comprehensively than previous research. Thereby, we cover the first two of the three 236 causal pathways to not experiencing grandparenthood pointed out by demographic 237 research (Margolis & Verdery, 2019): one's own childlessness, childlessness of one's children 238 during one's life, and (premature) death. Our comparative design also controls for average 239 age-related and historical trends in the Big Five traits and life satisfaction (Luhmann et 240 al., 2014), and enables us to report effects of the transition to grandparenthood 241 unconfounded by instrumentation effects, which describe the tendency of reporting lower 242 well-being scores with each repeated measurement (Baird et al., 2010).³ 243

We improve upon previous longitudinal studies utilizing matched control groups (e.g., Anusic et al., 2014a, 2014b; Yap et al., 2012) in that we performed the matching at a

³ Instrumentation effects caused by repeated assessments have only been described for life satisfaction but we assume similar biases exist for certain Big Five items.

256

257

258

259

261

262

263

264

271

specific time point preceding the transition to grandparenthood (at least two years 246 beforehand) and not based on individual survey years. This design choice ensures that the 247 covariates involved in the matching procedure are not already influenced by the event or 248 anticipation of it (Greenland, 2003; Rosenbaum, 1984; VanderWeele, 2019; VanderWeele et 249 al., 2020), thereby also reducing the risk of confounding through collider bias (Elwert & 250 Winship, 2014). Similar approaches in the study of life events have recently been adopted 251 (Balbo & Arpino, 2016; Krämer & Rodgers, 2020; van Scheppingen & Leopold, 2020). 252 Informed by the social investment principle and previous research on personality 253 development in middle adulthood and old age, we preregistered the following hypotheses 254 (prior to data analysis; osf.io/): 255

- H1a: Following the birth of their first grandchild, grandparents increase in agreeableness and conscientiousness, and decrease in neuroticism as compared to the matched control groups of parents (but not grandparents) and nonparents, but do not differ in their trajectories of extraversion and openness to experience.
- H1b: Grandparents' post-transition increases in agreeableness and conscientiousness, and decreases in neuroticism are more pronounced among those who provide substantial grandchild care.
- H1c: Grandmothers increase in life satisfaction following the transition to grandparenthood as compared to the matched control groups but grandfathers do not.
- H2: Individual differences in intraindividual change in the Big Five and life satisfaction are larger in the grandparent group than the control groups.
- H3a: Compared to the matched control groups, grandparents' rank-order stability of
 the Big Five traits over the transition to grandparenthood is smaller.
- H3b: Grandparents' rank-order stability of life satisfaction is comparatively stable over the transition to grandparenthood.
 - Exploratorily, we further probe the moderator performing paid work which could

constitute a potential role conflict among grandparents.

273 Methods

274 Samples

To evaluate these hypotheses, we used data from two population-representative 275 panel studies: the Longitudinal Internet Studies for the Social Sciences (LISS) panel from the Netherlands and the Health and Retirement Study (HRS) from the United States. The LISS panel is a representative sample of the Dutch population initiated in 2008 278 with data collection still ongoing (Scherpenzeel, 2011; van der Laan, 2009). It is 279 administered by CentERdata (Tilburg University, The Netherlands). Included households 280 are a true probability sample of households drawn from the population register 281 (Scherpenzeel & Das, 2010). While originally roughly half of invited households consented 282 to participate, refreshment samples were drawn in order to oversample previously 283 underrepresented groups using information about response rates and their association with 284 demographic variables (household type, age, ethnicity; see 285 https://www.lissdata.nl/about-panel/sample-and-recruitment/). Data collection was 286 carried out online and participants lacking the necessary technical equipment were 287 outfitted with it. We included yearly assessments from 2008 to 2020 from several different 288 modules (see *Measures*) as well as data on basic demographics which was assessed on a 280 monthly rate. For later coding of covariates from these monthly demographic data we used 290 the first available assessment in each year. 291 The HRS is an ongoing longitudinal population-representative study of older adults 292 in the US (Sonnega et al., 2014) administered by the Survey Research Center (University 293 of Michigan, United States). Initiated in 1992 with a first cohort of individuals aged 51-61 and their spouses, the study has since been extended with additional cohorts in the 1990s 295 (see https://hrs.isr.umich.edu/documentation/survey-design/). In addition to the HRS 296 core interview every two years (in-person or as a telephone survey), the study has since 297

298 2006 included a leave-behind questionnaire covering a broad range of psychosocial topics
299 including the Big Five personality traits and life satisfaction. These topics, however, were
300 only administered every four years starting in 2006 for one half of the sample and in 2008
301 for the other half. We included personality data from 2006 to 2018, all available data for
302 the coding of the transition to grandparenthood from 1996 to 2018, as well as covariate
303 data from 2006 to 2018 including variables drawn from the Imputations File and the
304 Family Data (only available up to 2014).

These two panel studies provided the advantage that they contained several waves 305 of personality data as well as information on grandparent status and a broad range of 306 covariates at each wave. While the HRS provided a large sample with a wider age range, 307 the LISS panel was smaller and younger⁴ but provided more frequent personality 308 assessments spaced every one to two years. Note that M. van Scheppingen has previously used the LISS panel to analyze correlated changes between life satisfaction and Big Five 310 traits across the lifespan (https://osf.io/3cxuy/). W. Chopik and M. van Scheppingen have 311 previously used the HRS to analyze Big Five traits and relationship-related constructs (van 312 Scheppingen et al., 2019). W. Chopik has additionally used the HRS to analyze mean-level 313 and rank-order changes in Big Five traits in response to be reavement (Chopik, 2018) and 314 other relationship-related or non-Big Five-related constructs (e.g., optimism; Chopik et al., 315 2020). These publications do not overlap with the current study in the central focus of 316 grandparenthood.⁵ The present study used de-identified archival data in the public 317 domain, and, thus, it was not necessary to obtain ethical approval from an IRB. 318

Measures

⁴ The reason for the included grandparents from the LISS panel being younger was that grandparenthood questions were part of the *Work and Schooling* module and—for reasons unknown to us—filtered to participants performing paid work. Thus, older, retired first-time grandparents from the LISS panel could not be identified.

⁵ Publications using LISS panel data can be searched at https://www.dataarchive.lissdata.nl/publications/. Publications using HRS data can be searched at https://hrs.isr.umich.edu/publications/biblio/.

20 Personality

In the LISS panel, the Big Five personality traits were assessed using the 50-item 321 version of the IPIP Big-Five Inventory scales (Goldberg, 1992). For each Big Five trait, ten 322 5-point Likert-scale items were answered (1 = very inaccurate, 2 = moderately inaccurate, 3 323 = neither inaccurate nor accurate, 4 = moderately accurate, 5 = very accurate). Example items included "Like order" (conscientiousness), "Sympathize with others' feelings" (agreeableness), "Worry about things" (neuroticism), "Have a vivid imagination" (openness 326 to experience), and "Start conversations" (extraversion). At each wave, we took a 327 participant's mean of each subscale as their trait score. Internal consistencies at the time of 328 matching, as indicated by McDonald's ω (McNeish, 2018), averaged $\omega = 0.83$ over all traits 329 ranging from $\omega = 0.76$ (conscientiousness in the nonparent control group) to $\omega = 0.90$ 330 (extraversion in the nonparent control group). Other studies have shown measurement 331 invariance for these scales across time and age groups, and convergent validity with the Big 332 Five inventory (BFI-2) (Denissen et al., 2020; Schwaba & Bleidorn, 2018). The Big Five 333 (and life satisfaction) were contained in the *Personality* module which was administered 334 yearly but with planned missingness in some years for certain cohorts (see Denissen et al., 335 2019). Thus, there are one to two years between included assessments, given no other 336 sources of missingness. 337 In the HRS, the Midlife Development Inventory (MIDI) scales were administered to 338 measure the Big Five (Lachman & Weaver, 1997). This instrument was constructed for use 339 in large-scale panel studies of adults and consisted of 26 adjectives (five each for 340 conscientiousness, agreeableness, and extraversion, four for neuroticism, and seven for openness to experience). Participants were asked to rate on a 4-point scale how well each item described them (1 = a lot, 2 = some, 3 = a little, 4 = not at all). Example adjectives included "Organized" (conscientiousness), "Sympathetic" (agreeableness), "Worrying" (neuroticism), "Imaginative" (openness to experience), and "Talkative" (extraversion). For 345 better comparability with the LISS panel, we reverse scored all items so that higher values

corresponded to higher trait levels and, at each wave, took the mean of each subscale as the trait score. Big Five trait scores showed satisfactory internal consistencies at the time of matching which averaged $\omega = 0.75$ over all traits ranging from $\omega = 0.66$ (conscientiousness in the nonparent control group) to $\omega = 0.81$ (agreeableness in the nonparent control group).

$_{ ext{351}}$ Life Satisfaction

In both samples, life satisfaction was assessed using the 5-item Satisfaction with Life Scale (SWLS; Diener et al., 1985) which participants answered on a 7-point Likert scale (1 strongly disagree, 2 = somewhat disagree, 3 = slightly disagree, 4 = neither agree or disagree, 5 = slightly agree, 6 = somewhat agree, 7 = strongly agree)⁶. An example item was "I am satisfied with my life". Internal consistency at the time of matching was ω = 0.89 in the LISS panel with the parent control sample (ω = 0.88 with the nonparent control sample), and ω = 0.91 in the HRS with the parent control sample (ω = 0.90 with the nonparent control sample).

360 Transition to Grandparenthood

The procedure to obtain information on grandparents' transition to 361 grandparenthood generally followed the same steps in both samples. The items this coding 362 was based on, however, differed slightly: In the LISS panel, participants were asked "Do 363 you have children and/or grandchildren?" with "children", "grandchildren", and "no 364 children or grandchildren" as possible answer categories. This question was part of the 365 Work and Schooling module and filtered to participants performing paid work. In the HRS, 366 all participants were asked for the total number of grandchildren: "Altogether, how many 367 grandchildren do you (or your husband / wife / partner, or your late husband / wife / 368 partner) have? Include as grandchildren any children of your (or your [late] husband's / 360 wife's / partner's) biological, step- or adopted children".

⁶ In the LISS panel, the "somewhat" was omitted and instead of "or" "nor" was used.

⁷ The listing of biological, step-, or adopted children has been added since wave 2006.

In both samples, we tracked grandparenthood status ($0 = no \ grandchildren$, 1 = at least one grandchild) over time. Due to longitudinally inconsistent data in some cases, we included in the grandparent group only participants with exactly one transition from 0 to 1 in this grandparenthood status variable, and no transitions backwards (see Fig. SX). We marked participants who continually indicated that they had no grandchildren as potential members of the control groups.

Covariates

For propensity score matching, we used a broad set of covariates (VanderWeele et 378 al., 2020) covering participants' demographics (e.g., education), economic situation (e.g., 379 income), and health (e.g., mobility difficulties). We also included the pre-transition 380 outcome variables as covariates—as recommended in the literature (Cook et al., 2020; 381 Hallberg et al., 2018; Steiner et al., 2010; VanderWeele et al., 2020), as well as the panel 382 wave participation count and assessment year in order to control for instrumentation effects 383 and historical trends (e.g., 2008/2009 financial crisis; Baird et al., 2010; Luhmann et al., 384 2014). For matching grandparents with the parent control group we additionally included 385 as covariates variables containing information on fertility and family history (e.g., number 386 of children, age of first three children) which were causally related to the timing of the 387 transition to grandparenthood (i.e., entry into treatment; Arpino, Gumà, et al., 2018; 388 Margolis & Verdery, 2019). 389 Covariate selection has seldom been explicitly discussed in previous longitudinal 390 studies estimating treatment effects of life events (e.g., in matching designs). We see two (in part conflicting) traditions that address covariate selection: First, classical recommendations from psychology argue to include all available variables that are 393 associated with both the treatment assignment process (i.e., selection into treatment) and 394 the outcome (e.g., Steiner et al., 2010; Stuart, 2010). Second, recommendations from a 395 structural causal modeling perspective (see Elwert & Winship, 2014; Rohrer, 2018) are 396

more cautious aiming to avoid pitfalls such as conditioning on a pre-treatment collider (collider bias) or a mediator (overcontrol bias). Structural causal modeling, however, requires advanced knowledge of the causal structures underlying all involved variables (Pearl, 2009).

In selecting covariates, we followed guidelines laid out by VanderWeele et al. (2019; 401 2020) which reconcile both views and offer practical guidance⁸ when complete knowledge of 402 the underlying causal structures is unknown: These authors propose a "modified 403 disjunctive cause criterion" (VanderWeele, 2019, p. 218) recommending to select all 404 available covariates which are assumed to be causes of the outcomes, treatment exposure 405 (i.e., the transition to grandparenthood), or both, as well as any proxies for an unmeasured 406 common cause of the outcomes and treatment exposure. To be excluded from this selection 407 are variables assumed to be instrumental variables (i.e., assumed causes of treatment exposure that are unrelated to the outcomes except through the exposure) and collider variables (Elwert & Winship, 2014). Because all covariates we used for matching were 410 measured at least two years before the birth of the grandchild, we judge the risk of 411 introducing collider bias or overcontrol bias by controlling for these covariates to be 412 relatively small. In addition, as mentioned in the *Introduction*, the event transition to 413 grandparenthood is not planned by or under direct control of grandparents which further 414 reduces the risk of bias introduced by controlling for pre-treatment colliders. 415

An overview of the variables we used to compute the propensity scores for matching
can be found in the Supplemental Material (see also Tables S2 & S3). Critically, we also
provide justification for each covariate on whether we assume it to be causally related to
treatment assignment, the outcomes, or both. We tried to find substantively equivalent
covariates in both samples but had to compromise in a few cases (e.g., children's
educational level only in HRS vs. children living at home only in LISS).

⁸ Practical considerations of covariate selection when using large archival datasets (i.e., with no direct control over data collection) are discussed in VanderWeele et al. (2020).

Estimating propensity scores requires complete covariate data. Therefore, before 422 computing propensity scores, we performed multiple imputations in order to account for 423 missingness in our covariates (Greenland & Finkle, 1995). Using five imputed data sets 424 computed by classification and regression trees (CART; Burgette & Reiter, 2010) in the 425 mice R package (van Buuren & Groothuis-Oudshoorn, 2011), we predicted treatment 426 assignment (i.e., the transition to grandparenthood) five times per observation in logistic 427 regressions with a logit link function.⁹ We averaged these five scores per observation to 428 compute the final propensity score to be used for matching (Mitra & Reiter, 2016). We 429 used imputed data only for propensity score computation and not in later analyses because 430 missing data in the outcome variables due to nonresponse was negligible. 431

Moderators

Based on insights from previous research, we tested three variables as potential 433 moderators of the mean-level trajectories of the Big Five and life satisfaction over the 434 transition to grandparenthood: First, we analyzed whether gender acted as a moderator as 435 indicated by research on life satisfaction (see Tanskanen et al., 2019; Di Gessa et al., 2019). 436 We coded a dummy variable indicating female gender (0 = male, 1 = female). 437 Second, we tested whether performing paid work or not was associated with 438 divergent trajectories of the Big Five and life satisfaction (see Schwaba & Bleidorn, 2019). 439 Since the LISS subsample of grandparents we identified was based exclusively on 440 participants performing paid work, we performed these analyses only in the HRS 441 subsample. This served two purposes: to test how participants involved in the workforce 442 (even if officially retired) differed from those not working, which might shed light on role 443 conflict. As a robustness check this also allowed us to assess whether potential differences in the main results between the LISS and HRS samples could be accounted for by

⁹ In these logistic regressions we included all covariates listed above as predictors except for *female* which was later used for exact matching and health-related covariates in LISS-wave 2014 which were not assessed in that wave.

including performing paid work as a moderator in analyses of the HRS sample. The LISS grandparent sample had already been conditioned on this variable through filtering in the questionnaire.

Third, we examined how involvement in grandchild care moderated trajectories of 449 the Big Five and life satisfaction in grandparents after the transition to grandparenthood 450 (see Arpino, Bordone, et al., 2018; Danielsbacka et al., 2019; Danielsbacka & Tanskanen, 451 2016). We coded a dummy variable (0 = provided less than 100 hours of grandchild care, 1 452 = provided 100 or more hours of grandchild care) as a moderator based on the question 453 "Did you (or your [late] husband / wife / partner) spend 100 or more hours in total since 454 the last interview / in the last two years taking care of grand- or great grandchildren?". ¹⁰ 455 This information was only available for grandparents in the HRS; in the LISS panel too few 456 participants answered follow-up questions on intensity of care (>50 in the final analysis sample).

459 Procedure

Drawing on all available data, three main restrictions defined the final analysis samples of grandparents (see Fig. SX for participant flowcharts): First, we identified participants who indicated having grandchildren for the first time during study participation (see *Measures*; $N_{LISS} = 337$; $N_{HRS} = 3272$, including HRS waves 1996-2004 before personality assessments were introduced). Second, we restricted the sample to participants with at least one valid personality assessment (valid in the sense that at least one of the six outcomes was non-missing; $N_{LISS} = 335$; $N_{HRS} = 1702$). Third, we included in the analysis samples only participants with both a valid personality assessment

¹⁰ Although dichotomization of a continuous construct (hours of care) is not ideal for moderation analysis (MacCallum et al., 2002), there were too many missing values in the variable assessing hours of care continuously (variables *E063).

¹¹ For the HRS subsample, we also excluded N=30 grandparents in a previous step who reported unrealistically high numbers of grandchildren (> 10) in their first assessment following the transition to grandparenthood.

```
before and one after the transition to grandparenthood (N_{LISS} = 253; N_{HRS} = 859).
468
    Lastly, few participants were excluded because of inconsistent or missing information
460
   regarding their children<sup>12</sup> resulting in the final analysis samples of first-time grandparents,
470
    N_{LISS} = 250 (53.60% female; age at transition to grandparenthood M = 57.94, SD = 4.87)
471
   and N_{HRS} = 846 (54.85% female; age at transition to grandparenthood M = 61.80, SD =
472
    6.88).
473
           To disentangle effects of the transition to grandparenthood from effects of being a
474
    parent, we defined two pools of potential control subjects to be involved in the matching
475
    procedure: The first pool of potential control subjects comprised parents who had at least
476
    one child in reproductive age (defined as 15 \leq age_{firstborn} \leq 65) but no grandchildren
477
   throughout the observation period (N_{LISS} = 844 with 3040 longitudinal observations;
478
    N_{HRS} = 1485 with 2703 longitudinal observations). The second pool of potential matches
    comprised participants who reported being childless throughout the observation period
    (N_{LISS} = 1077 \text{ with } 4337 \text{ longitudinal observations}; N_{HRS} = 1340 \text{ with } 2346 \text{ longitudinal})
481
    observations). The two control groups were, thus, by definition mutually exclusive.
482
           In order to match each grandparent with the control participant who was most
483
    similar in terms of the included covariates we utilized propensity score matching.
484
    Propensity score matching was performed in a grandparent's survey year which preceded
485
    the year when the transition was first reported by at least two years (aside from that
486
    choosing the smallest available gap between matching and transition). This served the
487
    purpose to ensure that the covariates used for matching were not affected by the event
488
    itself or its anticipation (i.e., when one's child was already pregnant with their first child;
489
    Greenland, 2003; Rosenbaum, 1984; VanderWeele et al., 2020). Propensity score matching
490
    was performed using the MatchIt R package (Ho et al., 2011) with exact matching on
491
    gender combined with Mahalanobis distance matching on the propensity score. In total,
492
```

¹² We opted not to use multiple imputation for these child-related variables such as number of children which defined the control groups and were also later used for computing the propensity scores.

four matchings were performed; two per sample (LISS; HRS) and two per control group
(parents but not grandparents; nonparents). We matched 1:1 with replacement because of
the relatively small pools of available non-grandparent controls. This meant that control
observations were allowed to be used multiple times for matching (i.e., duplicated in the
analysis samples¹³). We did not specify a caliper because our goal was to find matches for
all grandparents, and because we achieved satisfactory covariate balance this way.

We evaluated the matching procedure in terms of covariate balance and, graphically,
in terms of overlap of the distributions of the propensity scores and (non-categorical)
covariates (Stuart, 2010). Covariate balance as indicated by the standardized difference in
means between the grandparent and the controls after matching was satisfactory (see
Tables S2 & S3) lying below 0.25 as recommended in the literature (Stuart, 2010).
Graphically, differences between the distributions of the propensity score and the covariates
were also small and indicated no missing overlap (see Fig. SX).

After matching, each matched control observation received the same value as their matched grandparent in the *time* variable describing the temporal relation to treatment, and the control subject's other longitudinal observations were centered around this matched observation. Thereby, we coded a counterfactual transition time frame for each control subject. Due to left- and right censored longitudinal data (i.e., panel entry or attrition), we restricted the final analysis samples to six years before and six years after the transition as shown in Table S1. We analyzed unbalanced panel data where not every participant provided all person-year observations. The final LISS analysis samples, thus, contained 250 grandparents with 1368 longitudinal observations, matched with 250 control subjects with either 1257 (parent control group) or 1355 longitudinal observations (nonparent control

¹³ In the LISS data, 250 grandparent observations were matched with 250 control observations; these control observations corresponded to 186 unique person-year observations stemming from 130 unique participants for the parent control group, and to 174 unique person-year observations stemming from 107 unique participants for the nonparent control group. In the HRS data, 846 grandparent observations were matched with 846 control observations; these control observations corresponded to 568 unique person-year observations stemming from 482 unique participants for the parent control group, and to 485 unique person-year observations stemming from 401 unique participants for the nonparent control group.

group). The final HRS analysis samples contained 846 grandparents with 2262 longitudinal observations, matched with 846 control subjects with either 2091 (parent control group) or 2039 longitudinal observations (nonparent control group; see Table S1. In the HRS, there were a few additional missing values in the outcomes ranging from 13 to 53 longitudinal observations which will be listwise deleted in the respective analyses.

521 Analytical Strategy

Our design can be referred to as an interrupted time-series with a "nonequivalent no-treatment control group" (Shadish et al., 2002, p. 182) where treatment, that is, the transition to grandparenthood, is not deliberately manipulated.

First, to analyze mean-level changes, we used linear piecewise regression coefficients 525 in multilevel regression models with person-year observations nested within participants 526 and households (Hoffman, 2015). To model change over time in relation to the birth of the 527 first grandchild, we coded three piecewise regression coefficients: a before-slope representing 528 linear change in the years leading up to the transition to grandparenthood, an after-slope 520 representing linear change in the years after the transition, and a jump coefficient shifting 530 the intercept directly after the transition was first reported, thus representing sudden 531 changes that go beyond changes already modeled by the after-slope (see Table 532 @ref(tab:piecewise-coding-scheme for the coding scheme of these coefficients; Hoffman, 533 2015). Other studies of personality development have recently adopted similar piecewise 534 growth-curve models (e.g., Bleidorn & Schwaba, 2018; Krämer & Rodgers, 2020; Schwaba 535 & Bleidorn, 2019; van Scheppingen & Leopold, 2020).

All effects of the transition to grandparenthood on the Big Five and life satisfaction were modeled as deviations from patterns in the matched control groups by interacting the three piecewise coefficients with the binary treatment variable (0 = control, 1 =grandparent). In additional models, we interacted these coefficients with the binary moderator variables resulting in two- or three-way interactions. To test differences in the growth parameters between two groups in cases where these differences were represented by
multiple fixed-effects coefficients, we defined linear contrasts using the *linearHypothesis*command from the *car* R package (Fox & Weisberg, 2019). All models of mean-level
changes were estimated using maximum likelihood and included random intercepts but no
random slopes of the piecewise regression coefficients.

Second, to assess interindividual differences in intraindividual change in the Big 547 Five and life satisfaction we added random slopes to the models assessing mean-level 548 changes (see Denissen et al., 2019 for a similar approach). In other words, we allowed for 549 differences between individuals in their trajectories of change to be modeled, that is, 550 differences in the before-slope, after-slope, and jump coefficients. Because multiple 551 simultaneous random slopes are often not computationally feasible, we added random 552 slopes one at a time and used likelihood ratio test to determine whether the addition of the respective random slope led to a significant improvement in model fit. We plotted distributions of random slopes (for a similar approach, see Denissen et al., 2019; Doré & Bolger, 2018). To statistically test differences in the random slope variance between the 556 grandparent group and each control group, we respecified the multilevel models as 557 multi-group latent growth curve models (LGCM; Preacher et al., 2008) using the lavaan R 558 package (Rosseel, 2012). Next, we tested a LGCM with an equality constraint on the 559 grandparents' and control groups' variances of the latent slope against an unconstrained 560 LGCM. This was also done separately for the parent and nonparent control groups. 561

Third, to examine rank-order stability in the Big Five and life satisfaction over the transition to grandparenthood, we computed the test-retest correlation of measurements prior to the transition to grandparenthood (at the time of matching) with the first available measurement after the transition. To test the difference in test-retest stability between grandparents and either of the control groups, we then entered the pre-treatment measure as well as the treatment variable (0 = control, 1 = grandparent) and their interaction into multiple regression models predicting the Big Five and life satisfaction.

The interaction tested for significant differences in the test-retest stability between those who experienced the transition to grandparenthood and those who did not (for a similar approach, see Denissen et al., 2019; McCrae, 1993).

We used R (Version 4.0.4; R Core Team, 2021) and the R-packages lme4 (Version 1.1.26; Bates et al., 2015), and lmerTest (Version 3.1.3; Kuznetsova et al., 2017) for multilevel modeling, as well as tidyverse (Wickham et al., 2019) for data wrangling, and papaja (Aust & Barth, 2020) for reproducible manuscript production. Additional modeling details and a list of all software we used is provided in the Supplemental Material. In line with Benjamin et al. (2018), we set the α -level for all confirmatory analyses to .005.

extra	Extraversion	cp*020 - cp*065	0.05	0.06	0.02	-0.10
neur	Neuroticism	cp*023 - cp*068	-0.02	-0.10	-0.26	-0.01
open	Openness	cp*024 - cp*069	0.06	0.09	-0.16	-0.05
participation	Waves participated		-0.27	-0.24	0.09	-0.10
year	Year of assessment	wave	-0.23	-0.15	0.08	-0.15

Note. PSM = propensity score matching, ref. = reference category, f. = female, m. = male, NA = covariate not used in this sample. The standardized difference in means between the grandparent and the two control groups (parent and nonparent) was computed by $(\bar{x}_{gp} - \bar{x}_c)/(\hat{\sigma}_{gp})$. A rule of thumb says that this measure should ideally be below .25 (Stuart, 2010).

Table S3

Standardized Difference in Means for Covariates Used in Propensity Score Matching and the Propensity Score in the HRS

			Parent con	trol group	Nonparent co	ontrol group
Covariate	Description	Raw variable	Before PSM	After PSM	Before PSM	After PSM
pscore	Propensity score	/	0.92	0.00	1.45	0.00
female	Gender $(f.=1, m.=0)$	RAGENDER	-0.07	0.00	0.01	0.00
age	Age	RABYEAR	-0.46	-0.03	-1.02	0.06
